# Unique Equilibrium in a Model of Self-Fulfilling Currency Attacks

By STEPHEN MORRIS AND HYUN SONG SHIN\*

*Even though self-fulfilling currency attacks lead to multiple equilibria when fundamentals are common knowledge, we demonstrate the uniqueness of equilibrium when speculators face a small amount of noise in their signals about the fundamentals. This unique equilibrium depends not only on the fundamentals, but also on financial variables, such as the quantity of hot money in circulation and the costs of speculative trading. In contrast to multiple equilibrium models, our model allows analysis of policy proposals directed at curtailing currency attacks.* (JEL F31, D82)

Speculative attacks are sometimes triggered without warning, and without any apparent change in the economic fundamentals. Commentators who have attempted to explain episodes of speculative crises have pointed to the self-fulfilling nature of the belief in an imminent speculative attack. If speculators believe that a currency will come under attack, their actions in anticipation of this precipitate the crisis itself, while if they believe that a currency is not in danger of imminent attack, their inaction spares the currency from attack, thereby vindicating their initial beliefs.<sup>1</sup>

However, merely pointing to the self-fulfilling nature of beliefs leaves open a number of crucial questions. First, such an account leaves unexplained the actual *onset* of an at-

tack when it occurs. By most accounts, both the European Exchange Rate Mechanism (ERM) and the Mexican peso were "ripe" for attack for some time before the crises that brought them down in the early 1990's—at least two years in Europe and perhaps a year in Mexico (Barry Eichengreen and Charles Wyplosz, 1993; Rudiger Dornbusch and Alejandro M. Werner, 1994). At any point in those periods, concerted selling by speculators would have raised the costs of maintaining the exchange rate sufficiently high that the monetary authorities would have been forced to abandon the parity. Why did the attacks happen when they did? Conventional accounts resort to forces that operate outside the theoretical model in trying to explain the shift of expectations that precipitated the attack. Some of these informal accounts are more persuasive than others, but none can be fully compelling as a theoretical model of the onset of a currency crisis.

Secondly, merely pointing to the self-fulfilling nature of beliefs leaves open the policy issues associated with curbing speculative attacks. For example, it is often argued that increased capital mobility induced by lower transaction costs increases the likelihood of currency crises, and that judicious "throwing of sand" into the excessively well-oiled wheels of international finance will play a role in curbing speculative attacks (Eichengreen et al., 1995). However, an account that merely points to the self-fulfilling nature of beliefs cannot contribute to this debate, since the question of how the beliefs are determined is

We are grateful to Marcus Miller for encouraging us to pursue this topic and to Stephen Coate and John Driffill for advice during the preparation of this paper. We thank Anne Sibert for her comments as discussant at the CEPR conference on "Origins and Management of Financial Crises." The first author acknowledges the support of the Alfred P. Sloan Foundation. The second author acknowledges the support of the U.K. Economic and Social Research Council under Grant No. R000221556. Finally, we thank two anonymous referees for comments on an earlier version.

<sup>1</sup> This theme is explored in Robert P. Flood and Peter M. Garber (1984) and Maurice Obstfeld (1986, 1994, 1996). A closely related literature explores self-fulfilling debt crises; see Guillermo A. Calvo (1988), Jonathan Eaton and Raquel Fernandez (1995), and Harold L. Cole and Timothy J. Kehoe (1996).

beyond the scope of such an account. Any argument for or against the proposal has to resort to forces outside the formal theory.

We argue here that the apparent multiplicity of equilibria associated with self-fulfilling beliefs is the consequence of assuming too simple a picture of the role played by information in a speculative episode. Although market participants each have a window on to the world, the imperfect nature of such a vantage point generates a failure of common knowledge of the fundamentals. Thus, everyone may know that the fundamentals are sound, but it may not be that everyone knows that everyone knows this. Still higher orders of such uncertainty may be relevant. Uncertainty about other participants' beliefs is crucial to a speculative episode, since the onset of a speculative attack relies to a large extent on coordinated behavior of speculators. We propose a more realistic modelling of the information structure underlying speculative situations that enables us to pinpoint the forces which determine the onset of a speculative attack. When speculators observe an independent noisy signal of the state of fundamentals, common knowledge of the fundamentals no longer holds. This is enough to induce a unique equilibrium of the model, in which there is a critical state below which attack always occurs and above which attack never occurs.<sup>2</sup> The value of this critical state depends on financial variables such as the mass of speculators and the transaction costs associated with attacking the currency. As a consequence, we can say something about how this unique outcome depends on the parameters of the problem, such as the costs of speculation, the underlying strength of the economy, and the size of the pool of hot money in circulation.

Information plays a subtle role in speculative crises. What is important is not the amount of information, *per se*, but rather how public and transparent this information is. If market partic-

ipants are well informed about the fundamentals, but they are unsure of the information received by other participants, and hence unsure of the beliefs held by others, speculative attacks may be triggered even though everyone knows that the fundamentals are sound. Our analysis highlights the importance of the transparency of the conduct of monetary policy and its dissemination to the public.

## I. Model

Our model is concerned with the strategic interaction between the government and a group of speculators in the foreign exchange market that takes place against the backdrop of a competitive market for foreign exchange. The economy is characterized by a state of fundamentals  $\theta$ , which we assume to be uniformly distributed over the unit interval  $[0, 1]$ . The exchange rate in the absence of government intervention is a function of  $\theta$ , and is given by  $f(\theta)$ . We assume that  $f$  is strictly increasing in  $\theta$ , so that higher values of  $\theta$  correspond to "stronger fundamentals."

The exchange rate is initially pegged by the government at  $e^*$ , where  $e^* \geq f(\theta)$  for all  $\theta$ . Facing the government is a continuum of speculators who may take one of two actions. A speculator may either attack the currency by selling short one unit of the currency, or refrain from doing so. There is a cost  $t > 0$  associated with short-selling. If a speculator short-sells the currency and the government abandons the exchange rate peg, then the payoff at state  $\theta$  by attacking the currency is given by the fall in the exchange rate minus the transaction cost. Thus the speculator's payoff is  $e^* - f(\theta) - t$ . If the government defends the peg, then the speculator pays the transaction cost, but has no capital gain. Thus his payoff is  $-t$ . If the speculator chooses not to attack the currency, his payoff is zero.

The government derives a value  $v > 0$  from defending the exchange rate at the pegged level, but also faces costs of doing so. The cost of defending the peg depends on the state of the fundamentals, as well as the proportion of speculators who attack the currency. We denote by  $c(\alpha, \theta)$  the cost of defending the peg if proportion  $\alpha$  of the speculators attack the currency at the state  $\theta$ . The government's pay-

<sup>2</sup> Andrew Postlewaite and Xavier Vives (1987) discuss the role of information in selecting among multiple equilibria in the closely related context of bank runs. Our analysis builds on and extends the earlier incomplete information game analysis of Hans Carlsson and Eric E. van Damme (1993) and Morris et al. (1995).

FIGURE 1. COST AND BENEFIT TO THE GOVERNMENT IN MAINTAINING THE CURRENCY PEG

off to abandoning the exchange rate is thus zero while the payoff to defending the exchange rate is

$$v - c(\alpha, \theta).$$

We assume that  $c$  is continuous and is increasing in  $\alpha$  while decreasing in  $\theta$ . In particular, to make the problem economically interesting we will impose the following assumptions on the cost function and the floating exchange rate  $f(\theta)$ .

- $c(0, 0) > v$ . In the worst state of fundamentals, the cost of defending the currency is so high that it exceeds the value  $v$  even if no speculators attack.
- $c(1, 1) > v$ . If all the speculators attack the currency, then even in the best state of the fundamentals, the cost of defending the currency exceeds the value.
- $e^* - f(1) < t$ . In the best state of the fundamentals, the floating exchange rate  $f(1)$  is sufficiently close to the pegged level  $e^*$  such that any profit from the depreciation of the currency is outweighed by the transactions cost  $t$ .

Let us denote by  $\underline{\theta}$  the value of  $\theta$  which solves  $c(0, \theta) = v$ . In other words,  $\underline{\theta}$  is the value of

FIGURE 2. THE MANAGED EXCHANGE RATE AND THE EXCHANGE RATE IN THE ABSENCE OF INTERVENTION AS A FUNCTION OF THE STATE OF FUNDAMENTALS

$\theta$  at which the government is indifferent between defending the peg and abandoning it in the absence of any speculative selling. When  $\theta < \underline{\theta}$ , the cost of defending the currency exceeds the value, even if no speculators attack the currency (see Figure 1). At the other end, denote by  $\bar{\theta}$  the value of  $\theta$  at which  $f(\theta) = e^* - t$ , so that the floating exchange rate is below the peg by the amount of the cost of attack. When  $\theta > \bar{\theta}$ , then the floating exchange rate is sufficiently close to the peg that a speculator cannot obtain a positive payoff by attacking the currency (see Figure 2). Using the two benchmark levels of the state of fundamentals  $\underline{\theta}$  and  $\bar{\theta}$ , we can classify the state of fundamentals under three headings, according to the underlying strategic situation.

#### A. Tripartite Classification of Fundamentals

Assuming that  $\underline{\theta} < \bar{\theta}$ , we can partition the space of fundamentals into three intervals,<sup>3</sup> emphasized by Maurice Obstfeld (1996).

- In the interval  $[0, \underline{\theta}]$ , the value of defending the peg is outweighed by its cost irrespective

<sup>3</sup> This assumption will hold if  $v$  is large and  $t$  is small.

of the actions of the speculators. The government then has no reason to defend the currency. For this reason, we say that the currency is *unstable* if  $\theta \in [0, \underline{\theta}]$ .

- In the interval  $(\underline{\theta}, \bar{\theta})$ , the value of defending the currency is greater than the cost, provided that sufficiently few speculators attack the currency. In particular, if none of the speculators attacks, then the value of defending the currency is greater than the cost, and so the government will maintain the peg, which in turn justifies the decision not to attack. However, it is also the case that if all the speculators attack the currency, then the cost of defending the currency is too high, and the government will abandon the peg. Moreover, since  $\bar{\theta}$  is the right end point of this interval, a speculator will make a positive profit if the government were to abandon the peg at any state  $\theta$  in the interval  $(\underline{\theta}, \bar{\theta})$ , so that if a speculator believes that the currency peg will be abandoned, then attacking the currency is the rational action. For this reason, we say that the currency is *ripe for attack* if  $\theta \in (\underline{\theta}, \bar{\theta})$ .
- Finally, in the interval  $[\bar{\theta}, 1]$ , although the speculators can force the government to abandon the peg, the resulting depreciation of the currency is so small that they cannot recoup the cost of attacking the currency. Thus, even if a speculator were to believe that the currency will fall, the rational action is to refrain from attacking it. In other words, it is a dominant action not to attack. For this reason, we say that the currency is *stable* if  $\theta \in [\bar{\theta}, 1]$ .

The interesting range is the “ripe for attack” region. Suppose that the government’s decision on whether or not to defend the currency is determined purely by weighing up the costs and benefits, and that it makes its decision once all the speculators have made their decisions. Then, if all the speculators have perfect information concerning the realization of  $\theta$ , the “ripe for attack” region gives rise to the standard case of multiple equilibria due to the self-fulfilling nature of the speculators’ beliefs. If the speculators believe that the currency peg will be maintained, then it is optimal not to attack, which in turn induces the government to defend the currency, thereby vin-

dicating the speculators’ decisions not to attack the currency. On the other hand, if the speculators believe that the currency peg will be abandoned, the rational action is to attack the currency, which in turn induces the government to abandon the peg, vindicating the decision to attack. Given this multiplicity of equilibria, no definitive prediction can be made as to whether the currency will come under attack or not. We will now see, however, that the situation is very different when the speculators face a small amount of uncertainty concerning the fundamentals. Each state of fundamentals gives rise to a unique outcome.

### B. Game with Imperfect Information of Fundamentals

Suppose that the speculators each have a signal concerning the state of fundamentals, as in the following game.

- Nature chooses the state of fundamentals  $\theta$  according to the uniform density over the unit interval.
- When the true state is  $\theta$ , a speculator observes a signal  $x$  which is drawn uniformly from the interval  $[\theta - \varepsilon, \theta + \varepsilon]$ , for some small<sup>4</sup>  $\varepsilon > 0$ . Conditional on  $\theta$ , the signals are identical and independent across individuals. Based on the signal observed, a speculator decides whether or not to attack the currency.
- The government observes the realized proportion of speculators who attack the currency,  $\alpha$ , and observes  $\theta$ .

The payoffs of the game follow from the description of the model above. We assume that if a speculator is indifferent between attacking and not attacking, he will refrain from attacking and that if the government is indifferent between defending the peg and abandoning it, it will choose to abandon it.<sup>5</sup>

An equilibrium for this game consists of strategies for government and for the contin-

<sup>4</sup> In particular, we assume that  $2\varepsilon < \min\{\underline{\theta}, 1 - \bar{\theta}\}$ .

<sup>5</sup> Nothing substantial hinges on these assumptions, which are made for purposes of simplifying the statement of our results.

uum of speculators such that no player has an incentive to deviate. We can solve out the government's strategy at the final stage of the game, to define a reduced-form game between the speculators only. To do this, consider the critical proportion of speculators needed to trigger the government to abandon the peg at state  $\theta$ . Let  $a(\theta)$  denote this critical mass. In the "unstable" region  $a(\theta) = 0$ , while elsewhere  $a(\theta)$  is the value of  $\alpha$  which solves  $c(\alpha, \theta) = v$ . Figure 3 depicts this function, which is continuous and strictly increasing in  $\theta$  where it takes a positive value, and is bounded above by 1.

The unique optimal strategy for the government is then to abandon the exchange rate only if the observed fraction of deviators,  $\alpha$ , is greater than or equal to the critical mass  $a(\theta)$  in the prevailing state  $\theta$ .

Taking as given this optimal strategy for the government, we can characterize the payoffs in the reduced-form game between the speculators. For a given profile of strategies of the speculators, we denote by

$$\pi(x)$$

the proportion of speculators who attack the currency when the value of the signal is  $x$ . We denote by  $s(\theta, \pi)$  the proportion of speculators who end up attacking the currency when the state of fundamentals is  $\theta$ , given aggregate selling strategy  $\pi$ . Since signals are uniformly distributed over  $[\theta - \varepsilon, \theta + \varepsilon]$  at  $\theta$ , we have<sup>6</sup>

$$(1) \quad s(\theta, \pi) = \frac{1}{2\varepsilon} \int_{\theta-\varepsilon}^{\theta+\varepsilon} \pi(x) dx.$$

Denote by  $A(\pi)$  the event where the government abandons the currency peg if the speculators follow strategy  $\pi$ :

$$(2) \quad A(\pi) = \{ \theta | s(\theta, \pi) \geq a(\theta) \}.$$

We can then define the payoffs of a reduced-form game between the speculators. The payoff to a speculator of attacking the currency at

FIGURE 3. THE PROPORTION OF SPECULATORS WHOSE SHORT SALES ARE SUFFICIENT TO INDUCE DEPRECIATION, EXPRESSED AS A FUNCTION OF THE FUNDAMENTALS

state  $\theta$  when aggregate short sales are given by  $\pi$  is

$$(3) \quad h(\theta, \pi)$$

$$= \begin{cases} e^* - f(\theta) - t & \text{if } \theta \in A(\pi) \\ -t & \text{if } \theta \notin A(\pi). \end{cases}$$

However, a speculator does not observe  $\theta$  directly. The payoff to attacking the currency must be calculated from the posterior distribution over the states conditional on the signal  $x$ . The expected payoff to attacking the currency conditional on the signal  $x$  is given by the expectation of (3) conditional on  $x$ . Denoting this by  $u(x, \pi)$ , we have

$$(4) \quad u(x, \pi)$$

$$\begin{aligned} &= \frac{1}{2\varepsilon} \int_{x-\varepsilon}^{x+\varepsilon} h(\theta, \pi) d\theta \\ &= \frac{1}{2\varepsilon} \left[ \int_{A(\pi) \cap [x-\varepsilon, x+\varepsilon]} (e^* - f(\theta)) d\theta \right] - t. \end{aligned}$$

<sup>6</sup> The following formula is for  $\theta \in [\varepsilon, 1 - \varepsilon]$ ; for  $\theta$  close to 0 or 1, the limits of the integration must be adjusted accordingly.

Since a speculator can guarantee a payoff of zero by refraining from attacking the currency, the rational decision conditional on signal  $x$  depends on whether  $u(x, \pi)$  is positive or negative. Thus if the government follows its unique optimal strategy,  $\pi$  is an equilibrium of the first period game if  $\pi(x) = 1$  whenever  $u(x, \pi) > 0$  and  $\pi(x) = 0$  whenever  $u(x, \pi) \leq 0$ .

## II. Unique Equilibrium

We now state the main result of our paper, noting the contrast between the multiplicity of possible outcomes when there is perfect information of the fundamentals against the uniqueness of outcome when there is a small amount of noise.

**THEOREM 1:** *There is a unique  $\theta^*$  such that, in any equilibrium of the game with imperfect information, the government abandons the currency peg if and only if  $\theta \leq \theta^*$ .*

The argument for our result can be presented in three steps.

**LEMMA 1:** *If  $\pi(x) \geq \pi'(x)$  for all  $x$ , then  $u(x, \pi) \geq u(x, \pi')$  for all  $x$ .*

In other words, if we compare two strategy profiles  $\pi$  and  $\pi'$ , where  $\pi$  entails a greater proportion of speculators who attack for any message  $x$ , then the payoff to attacking the currency is greater given  $\pi$  than when it is given by  $\pi'$ . Thus speculators' decisions to attack the currency are strategic complements.

### PROOF OF LEMMA 1:

Since  $\pi(x) \geq \pi'(x)$ , we have  $s(\theta, \pi) \geq s(\theta, \pi')$  for every  $\theta$ , from the definition of  $s$  given by (1). Thus, from (2),

$$A(\pi) \supseteq A(\pi').$$

In other words, the event in which the currency peg is abandoned is strictly larger under  $\pi$ . Then, from (4) and the fact that  $e^* - f(\theta)$  is nonnegative,

$$\begin{aligned} & u(x, \pi) \\ &= \frac{1}{2\epsilon} \left[ \int_{A(\pi) \cap [x-\epsilon, x+\epsilon]} (e^* - f(\theta)) d\theta \right] - t \\ &\geq \frac{1}{2\epsilon} \left[ \int_{A(\pi') \cap [x-\epsilon, x+\epsilon]} (e^* - f(\theta)) d\theta \right] - t \\ &= u(x, \pi'), \end{aligned}$$

which proves the lemma.

For the next step, consider the strategy profile where every speculator attacks the currency if and only if the message  $x$  is less than some fixed number  $k$ . Then, aggregate short sales  $\pi$  will be given by the indicator function  $I_k$ , defined as

$$(5) \quad I_k(x) = \begin{cases} 1 & \text{if } x < k \\ 0 & \text{if } x \geq k \end{cases}$$

When speculators follow this simple rule of action, the expected payoff to attacking the currency satisfies the following property.

**LEMMA 2:**  *$u(k, I_k)$  is continuous and strictly decreasing in  $k$ .*

In other words, when aggregate short sales are governed by  $I_k$ , and we consider the payoff to attacking the currency given the marginal message  $k$ , this payoff is decreasing as the fundamentals of the economy become stronger. Put another way, when the fundamentals of the economy are stronger, the payoff to attacking the currency is lower for a speculator on the margin of switching from attacking to not attacking. Such a property would be a reasonable feature of any model of currency attacks where the government is able to resist speculators better when the fundamentals are stronger.

The proof of Lemma 2 is simple but involves some algebraic manipulation, and hence is presented separately in the Appendix. Taking Lemma 2 as given, we can then prove the following result.

**LEMMA 3:** *There is a unique  $x^*$  such that, in any equilibrium of the game with imperfect*

*information of the fundamentals, a speculator with signal  $x$  attacks the currency if and only if  $x < x^*$ .*

To prove this, we begin by establishing that there is a unique value of  $k$  at which

$$u(k, I_k) = 0.$$

From Lemma 2, we know that  $u(k, I_k)$  is continuous and strictly decreasing in  $k$ . If we can show that it is positive for small values of  $k$  and negative for large values, then we can guarantee that  $u(k, I_k) = 0$  for some  $k$ . When  $k$  is sufficiently small (i.e.,  $k \leq \underline{\theta} - \varepsilon$ ), the marginal speculator with message  $k$  knows that the true state of fundamentals is in the "unstable" region, since such a message is consistent only with a realization of  $\theta$  in the interval  $[0, \underline{\theta}]$ . Since the payoff to attacking the currency is positive at any  $\theta$  in this interval, we have  $u(k, I_k) > 0$ . Similarly, when  $k$  is sufficiently large (i.e.,  $k \geq \bar{\theta} + \varepsilon$ ), the marginal speculator with message  $k$  knows that the true state of fundamentals is in the "stable" region. Since the payoff to attacking is negative at every state in this region, we have  $u(k, I_k) < 0$ . Hence, there is a unique value of  $k$  for which  $u(k, I_k) = 0$ , and we define the value  $x^*$  as this unique solution to  $u(k, I_k) = 0$ .

Now, consider any equilibrium of the game, and denote by  $\pi(x)$  the proportion of speculators who attack the currency given message  $x$ . Define the numbers  $\underline{x}$  and  $\bar{x}$  as

$$\underline{x} = \inf \{x | \pi(x) < 1\}$$

$$\text{and } \bar{x} = \sup \{x | \pi(x) > 0\}.$$

Since  $\bar{x} \geq \sup \{x | 0 < \pi(x) < 1\} \geq \inf \{x | 0 < \pi(x) < 1\} \geq \underline{x}$ ,

$$(6) \quad \underline{x} \leq \bar{x}.$$

When  $\pi(x) < 1$ , there are some speculators who are not attacking the currency. This is only consistent with equilibrium behavior if the payoff to not attacking is at least as high as the payoff to attacking given message  $x$ . By continuity, this is true at  $\underline{x}$  also. In other words,

$$(7) \quad u(\underline{x}, \pi) \leq 0.$$

Now, consider the payoff  $u(x, I_x)$ . Clearly,  $I_{\underline{x}} \leq \pi$ , so that Lemma 1 and (7) imply  $u(\underline{x}, I_{\underline{x}}) \leq u(\underline{x}, \pi) \leq 0$ . Thus,  $u(\underline{x}, I_{\underline{x}}) \leq 0$ . Since we know from Lemma 2 that  $u(k, I_k)$  is decreasing in  $k$  and  $x^*$  is the unique value of  $k$  which solves  $u(k, I_k) = 0$ , we have

$$(8) \quad \underline{x} \geq x^*.$$

A symmetric argument establishes that

$$(9) \quad \bar{x} \leq x^*.$$

Thus, from (8) and (9), we have  $\underline{x} \geq x^* \geq \bar{x}$ . However, we know from (6) that this implies

$$\underline{x} = x^* = \bar{x}.$$

Thus, the equilibrium  $\pi$  is given by the step function  $I_{x^*}$ , which is what Lemma 3 states. Hence, this proves Lemma 3.

From this, it is a short step to the proof of our main theorem itself. Given that equilibrium  $\pi$  is given by the step function  $I_{x^*}$ , the aggregate short sales at the state  $\theta$  are given by

$$s(\theta, I_{x^*}) = \begin{cases} 1 & \text{if } \theta < x^* - \varepsilon \\ \frac{1}{2} - \frac{1}{2\varepsilon} (\theta - x^*) & \text{if } x^* - \varepsilon \leq \theta < x^* + \varepsilon \\ 0 & \text{if } \theta \geq x^* + \varepsilon. \end{cases}$$

Aggregate short sales  $s(\theta, I_{x^*})$  are decreasing in  $\theta$  when its value is strictly between 0 and 1, while  $a(\theta)$  is increasing in  $\theta$  for this range. See Figure 4, which illustrates the derivation of the cutoff point for the state of fundamentals at which the equilibrium short sales are equal to the short sales which induce depreciation.

We know that  $x^* > \underline{\theta} - \varepsilon$ , since otherwise attacking the currency is a strictly better action, contradicting the fact that  $x^*$  is a switching point. Thus,  $s(\theta, I_{x^*})$  and  $a(\theta)$  cross precisely once. Define  $\theta^*$  to be the value of  $\theta$  at which these two curves cross. Then,  $s(\theta, I_{x^*}) \geq a(\theta)$  if and only if  $\theta \leq \theta^*$ , so that the government abandons the currency peg if and only if  $\theta \leq \theta^*$ . This is the claim of our main theorem.

FIGURE 4. THE DERIVATION OF THE CUTOFF POINT FOR THE STATE OF FUNDAMENTALS AT WHICH THE EQUILIBRIUM SHORT SALES ARE EQUAL TO THE SHORT SALES WHICH INDUCE DEPRECIATION

### III. Comparative Statics and Policy Implications

#### A. Changes in the Information Structure

When there is no noise, there are multiple equilibria throughout the "ripe for attack" region of fundamentals. But when there is positive noise, there is a unique equilibrium with critical value  $\theta^*$ . The value of  $\theta^*$  in the limit as  $\epsilon$  tends to zero has a particularly simple characterization.

**THEOREM 2:** *In the limit as  $\epsilon$  tends to zero,  $\theta^*$  is given by the unique solution to the equation  $f(\theta^*) = e^* - 2t$ .*

The proof is in the Appendix. Intuition is gained by considering the marginal speculator who observes message  $x = \theta^*$ . With  $\epsilon$  small, this tells the speculator that the true  $\theta$  is close to  $\theta^*$ . Since the government abandons the peg if and only if  $\theta$  is less than  $\theta^*$ , he attaches equal probability to the currency being abandoned and defended. So, the expected payoff to attacking is  $\frac{1}{2}(e^* - f(\theta^*))$ , while the cost is  $t$ . For the marginal speculator, these are equal, leading to the equation in Theorem 2.

Information plays a subtle role in the model. What matters is not the amount of information, per se, but whether there is common knowledge. With noise, it is never common knowledge that the fundamentals are consistent with the government maintaining the currency peg, i.e., that  $\theta \geq \underline{\theta}$ . If you observe a signal greater than  $\underline{\theta} + \epsilon$ , then you can claim to *know* that  $\theta \geq \underline{\theta}$ , since your message has the margin of error of  $\epsilon$ . When do you know that *everyone* knows that  $\theta \geq \underline{\theta}$ ? In other words, when do you know that everyone has observed a signal greater than  $\underline{\theta} + \epsilon$ ? Since others' signals can differ from yours by at most  $2\epsilon$ , this will be true if you observe a signal greater than  $\underline{\theta} + 3\epsilon$ . Proceeding in this way, there is " $n$ th order knowledge" that  $\theta \geq \underline{\theta}$  (i.e., everyone knows that everyone knows ... ( $n$  times) that everyone knows it) exactly if everyone has observed a signal greater than or equal to  $\underline{\theta} + (2n - 1)\epsilon$ . But, by definition, there is common knowledge that  $\theta \geq \underline{\theta}$  if and only if there is  $n$ th order knowledge for every  $n$ . But for any fixed  $\epsilon$  and signal  $x$ , there will be some level  $n$  at which  $n$ th order iterated knowledge fails. Thus it is never common knowledge that  $\theta$  is not in the unstable region.

One interpretation we may put on noisy information is that the recipients of the differential information learn of the true underlying fundamentals of the economy with little error, but that there are small discrepancies in how these messages are interpreted by the recipients. When looking for a cause or a trigger for a currency attack, we should look for the arrival of noisy information, i.e., news events that are not interpreted in exactly the same way by different speculators. The informational events that matter may be quite subtle. A "grain of doubt," allowing that others may believe that the economy is, in fact, unstable, will lead to a currency crises even if everyone knows that the economy is not unstable. In predicting when crises will occur, average opinion or even extreme opinion need not precipitate a crisis. Rather, what matters is the higher order beliefs of some participants who are apprehensive about the beliefs of others, concerning the beliefs of yet further individuals, on these extreme opinions. This interpretation may shed light on some accounts of recent currency crises. Rumors of political

trouble in Chiapas Province were widely cited as a cause of the 1994 Mexico crisis (*New York Times*, 1994); uncertainty about Maastricht, German unification, and Bundesbank pronouncements were argued to be important in the 1992 European Monetary System crises. Our analysis suggests that such "informational events" might precipitate a crisis even if no investor thought they conveyed real information about fundamentals themselves. It is enough that the announcements remove common knowledge that the fundamentals were sustainable.

Above all, our analysis suggests an important role for public announcements by the monetary authorities, and more generally, the transparency of the conduct of monetary policy and its dissemination to the public. If it is the case that the onset of currency crises may be precipitated by higher-order beliefs, even though participants believe that the fundamentals are sound, then the policy instruments which will stabilize the market are those which aim to restore transparency to the situation, in an attempt to restore common knowledge of the fundamentals. The most effective means towards this would be a prominent public announcement which is commonly known to convey information to all relevant participants. The canonical case of a communication arrangement which would be conducive to achieving common knowledge is the "town hall meeting" in which an announcement is made to an audience gathered in a single room, where everyone can observe that all other participants are in an identical position. In contrast, if the audience is fragmented, and must communicate in small groups, common knowledge is extremely difficult to achieve.<sup>7</sup> The Clinton administration's announcement of the \$40 billion dollar rescue package for the Mexican peso can be seen as an attempt to restore the sort of transparency referred to above. Its effectiveness derived more from its very public nature, rather than the actual sum of money involved. This suggests a crucial

role for the timely and effective dissemination of information on the part of policy makers, and the smooth functioning of a reliable and transparent set of communication channels between market participants and the policy makers, as well as between the market participants themselves.

### B. Changes in Transaction Costs

We next examine shifts in  $t$ . Drawing on Theorem 2, which determines  $\theta^*$  in the limit as  $\epsilon$  becomes small, we can totally differentiate the equation  $f(\theta^*) = e^* - 2t$  to obtain

$$\frac{d\theta^*}{dt} = -\frac{2}{f'(\theta^*)}.$$

Thus increasing transaction costs prevents currency crises, since it reduces the range of fundamentals where an attack occurs. The size of this effect depends on the slope of  $f$ : when the  $f'$  is small, an increase in the cost of speculation has a large effect on the switching point  $\theta^*$ . This suggests that the imposition of small transactions costs as advocated by several commentators will have a large impact on the prevalence of speculation precisely when the *consequences* of such speculative attacks are small. If speculative attacks are predicted to lead to drastic effects (i.e., when  $f(\theta)$  is a steep function of  $\theta$ ), then the imposition of a small additional cost is unlikely to have a large effect on the incidence of currency attacks.

### C. Changes in Aggregate Wealth

Now consider how our analysis is affected when aggregate wealth varies. The international flow of so-called "hot money" would be one factor in determining this aggregate wealth, as well as changes in the numbers of speculators themselves. The main effect of a change in aggregate wealth of the speculators is a change in the function  $a(\theta)$ , which indicates the critical proportion of speculators needed to attack the currency in order to induce the government to abandon the currency peg. When the aggregate wealth of the speculators increases, then this critical proportion of speculators falls, since the government's decision is based on the absolute level of short sales.

<sup>7</sup> Ariel Rubinstein's (1989) e-mail game is a case in point, and Michael S.-Y. Chwe (1996) has suggested some of the relevant factors which would allow us to address this issue in a more general context.

As can be seen from Figure 4, a downward shift in the  $a(\theta)$  function has the effect of enlarging the set of states at which the government abandons the exchange rate peg. In other words the event  $A(\pi) = \{\theta | s(\theta, \pi) > a(\theta)\}$  is strictly larger with a lower  $a(\cdot)$  function. Since the payoff to speculation is given by

$$\int_{A(\pi) \cap [x - \varepsilon, x + \varepsilon]} (e^* - f(\theta)) d\theta - t,$$

the enlargement of the event  $A(\pi)$  has an unambiguous effect in increasing the payoff to attacking the currency at any value of the signal  $x$ . Thus, the benchmark value  $\theta^*$  is shifted to the right, and the incidence of speculative attacks increases.

Note, however, from Figure 4 that the effect of an increase in the  $a(\cdot)$  function depends on the size of the noise  $\varepsilon$ . The effect is largest when  $\varepsilon$  is also large. In the limiting case when  $\varepsilon$  tends to zero, the equilibrium  $s(\theta, I_{x^*})$  becomes the step function  $I_{x^*}$ , so that a shift in the  $a(\cdot)$  function has no effect on the switching point  $\theta^*$ . Thus, our analysis suggests that changes in the aggregate wealth of speculators need not have a large impact on the incidence of currency attacks when the speculators have fairly precise information concerning the fundamentals. It is when the noise is large that shifts in wealth have a big impact.

This suggests that the imposition of direct capital controls work best when there is a lack of "transparency" of the economic fundamentals, in the sense that observers differ widely in their interpretation of the economic fundamentals. When the fundamentals are relatively transparent to all (corresponding to a small  $\varepsilon$ ), direct capital controls seem far less effective. Under such circumstances, strategic considerations dominate any uncertainty concerning the fundamentals.

#### IV. Conclusion

Existing models of currency attacks that focus on fundamentals ignore the role of speculators' beliefs about other speculators' behavior. Existing self-fulfilling beliefs models of currency attacks assume that speculators know (in equilibrium) exactly what other speculators will do. Neither feature is realistic. Our

model takes neither extreme. Because there is some uncertainty about equilibrium, speculators are uncertain as to exactly what other speculators will do; but their behavior depends nontrivially on what they believe they will do. Because our model of self-fulfilling currency attacks is consistent with unique equilibrium, we are able to analyze the impact of alternative policies.

#### APPENDIX

##### PROOF OF LEMMA 2:

Consider the function  $s(\theta, I_k)$ , which gives the proportion of speculators who attack the currency at  $\theta$  when the aggregate short sales is given by the step function  $I_k$ . Since  $x$  is uniformly distributed over  $[\theta - \varepsilon, \theta + \varepsilon]$ , we have

$$(A1) \quad s(\theta, I_k) = \begin{cases} 1 & \text{if } \theta \leq k - \varepsilon \\ \frac{1}{2} - \frac{1}{2\varepsilon}(\theta - k) & \text{if } k - \varepsilon \leq \theta \leq k + \varepsilon \\ 0 & \text{if } \theta \geq k + \varepsilon. \end{cases}$$

If aggregate short sales are given by  $I_k$ , there is a unique  $\theta$  (which depends on  $k$ ) where the mass of speculators attacking equals the mass of speculators necessary to cause the government to abandon the exchange rate [where  $s(\theta, I_k) = a(\theta)$ ]. Write  $\psi(k)$  for the amount that  $\theta$  must exceed  $k$  in order for this to be true. In other words,  $\psi(k)$  is the unique value of  $\psi$  solving  $s(k + \psi, I_k) = a(k + \psi)$ . Observe that  $\psi(k) = \varepsilon$  if  $k \leq \theta - \varepsilon$ , while if  $k > \theta - \varepsilon$ , then  $-\varepsilon < \psi(k) < \varepsilon$  and is the value of  $\psi$  solving  $(1/2 - \psi/2\varepsilon) = a(k + \psi)$ .

Since the government abandons the currency peg if and only if  $\theta$  lies in the interval  $[0, k + \psi(k)]$ , the payoff function  $u(k, I_k)$  is given by

$$(A2) \quad \frac{1}{2\varepsilon} \int_{k - \varepsilon}^{k + \psi(k)} (e^* - f(\theta)) d\theta - t.$$

Since  $e^* - f(\theta)$  is strictly decreasing in  $\theta$ , if we can show that  $\psi(k)$  is weakly decreasing in  $k$ , this will be sufficient to show that  $u(k, I_k)$  is strictly decreasing in  $k$ . To see that  $\psi(k)$

is weakly decreasing in  $k$ , totally differentiate the equation  $(1/2 - \psi/2\epsilon) = a(k + \psi)$  with respect to  $k$ , to obtain  $-(1/2\epsilon)\psi'(k) = a'(\theta)(1 + \psi'(k))$ . Hence,

$$\psi'(k) = -\frac{a'(\theta)}{a'(\theta) + (1/2\epsilon)} \leq 0,$$

which is sufficient for  $u(k, I_k)$  to be strictly decreasing in  $k$ . Finally, the continuity of  $u(k, I_k)$  follows immediately from the fact that it is an integral in which the limits of integration are themselves continuous in  $k$ . This completes the proof of Lemma 2.

#### PROOF OF THEOREM 2:

Consider the switching point  $x^*$ , which is the solution to the equation  $u(x^*, I_{x^*}) = 0$ . Then, writing  $F(\epsilon) = \int_{A(I_{x^*}) \cap [x^* - \epsilon, x^* + \epsilon]} (e^* - f(\theta)) d\theta$ , we can express this equation as  $(F(\epsilon)/2\epsilon) - t = 0$ . By using L'Hôpital's rule,

$$\lim_{\epsilon \rightarrow 0} \frac{F(\epsilon)}{2\epsilon} = \frac{F'(0)}{2} = \frac{e^* - f(x^*)}{2}.$$

Thus, in the limit as  $\epsilon \rightarrow 0$ , equation (A3) yields  $f(x^*) = e^* - 2t$ . Finally, we note that  $x^*$  converges to  $\theta^*$  when  $\epsilon$  tends to zero, since in the limit,  $s(\theta, I_{x^*}) = I_{x^*}$ .
